

## Lecture 2: Introduction to statistical computing

*Lecturer: Bo Y.-C. Ning**January 11, 2022*

**Disclaimer:** *My notes may contain errors, distribution outside this class is allowed only with the permission of the Instructor.*

## Announcement

- Sign up Piazza; remote teaching continue to Jan 28, 2022
- Homework 1 posted, due January 26, 11:59pm
- Discussion sessions this week: A01 Numpy and the Jupyter Notebook and A02 RMarkdown
- Discussion sessions Zoom link: <https://ucdavis.zoom.us/j/92671467118>

## Today

- Review of linear algebra (self-study)
- Introduction to scientific computing

## 1 Review of linear algebra (continue, self-study)

Useful book: *The Matrix Cookbook*: <https://www.math.uwaterloo.ca/~hwolkowi/matrixcookbook.pdf>

### 1.1 Trace

$A$  is a square matrix,  $A \in \mathbb{R}^{n \times n}$

- $\text{tr}(A) = \sum_{i=1}^n a_{ii}$
- $\text{tr}(A + B) = \text{tr}(A) + \text{tr}(B)$
- $\text{tr}(\lambda A) = \lambda \text{tr}(A)$
- $\text{tr}(A') = \text{tr}(A)$
- In general,  $\text{tr}(A_1 A_2 \dots A_k) = \text{tr}(A_k A_1 \dots A_{k-1}) = \text{tr}(A_{j+1} \dots A_k A_1 \dots A_j)$

## 1.2 Determinant

- If  $A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}$ ,  $\det(A) = a_{11}a_{22} - a_{12}a_{21}$ .
- $\det(AB) = \det(A)\det(B)$  for  $A, B \in \mathbb{R}^{n \times n}$
- $\det A^{-1} = 1/\det(A)$
- $\det(A) = \det(A')$  and, for a scalar  $c$  and  $A \in \mathbb{R}^{n \times n}$ ,  $\det(cA) = c^n \det(A)$
- The determinant of an upper or lower triangular matrix is the product of its diagonal elements.
- $A$  is nonsingular (or positive definite) if and only if  $\det(A) \neq 0$
- $A$  is singular if and only if  $\det(A) = 0$
- If  $M = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$  is a block matrix,  $A \in \mathbb{R}^{m \times m}$ ,  $B \in \mathbb{R}^{m \times n}$ ,  $C \in \mathbb{R}^{n \times m}$ , and  $D \in \mathbb{R}^{n \times n}$ , then

$$\det(M) = \det(A - BD^{-1}C)\det(D) = \det(A)\det(D - CA^{-1}B)$$

## 1.3 Singular value decomposition (SVD)

For  $A \in \mathbb{R}^{m \times n}$  and  $p = \min\{m, n\}$

- Singular value decomposition:  $A = U\Sigma V'$ , where
  - $U = (u_1, \dots, u_m) \in \mathbb{R}^{m \times m}$  is orthogonal
  - $V = (v_1, \dots, v_p) \in \mathbb{R}^{n \times n}$  is orthogonal
  - $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_p) \in \mathbb{R}^{m \times n}$ ,  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_p \geq 0$
  - $\sigma_i$  are called the singular values,  $u_i$  are the left singular vectors, and  $v_i$  are the right singular vectors.
- Thin (compact) SVD: assume  $m \geq n$ ,  $A = U\Sigma V'$ , where
  - $U \in \mathbb{R}^{m \times n}$ ,  $U'U = I_n$
  - $V \in \mathbb{R}^{n \times n}$ ,  $V'V = I_n$
  - $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n) \in \mathbb{R}^{m \times n}$ ,  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n \geq 0$
- Relation to eigen-decomposition. Using thin SVD:

$$A'A = V\Sigma U U' \Sigma V' = V\Sigma^2 V'$$

$$AA' = U\Sigma V V' \Sigma U' = U\Sigma^2 U'$$

- Application: Principal component analysis (dimension deduction)
  - Principal components are eigenvectors of the covariance matrix (example: <https://arxiv.org/pdf/1708.00491.pdf>)

## 2 Introduction to statistical computing

### 2.1 How Gauss became famous?

1801 Dr Carl Friedrich Gauss at the year 24 proved Fundamental Theorem of Algebra. He wrote the book *Disquisitiones Arithmeticae*, which is still being studied today

1801 Jan 1 - Feb 11 (41 days), astronomer Piazzi observed Ceres (a dwarf planet), which was then lost behind sun

1801 From August to September, futile search by top astronomers; Laplace claimed it unsolvable

1801 From October to November, Gauss did calculations by method of least squares

1801 On December 31, astronomer von Zach relocated Ceres according to Gauss' calculation

1802 *Summarische Übersicht der Bestimmung der Bahnen der beiden neuen Hauptplaneten angewandten Methoden*, considered the origin of linear algebra

1807 Professor of Astronomy and Director of Göttingen Observatory in remainder of his life

1809 *Theoria motus corporum coelestium in sectionibus conicis solem ambientum* (Theory of motion of the celestial bodies moving in conic sections around the Sun); birth of the Gaussian (normal) distribution, as an attempt to rationalize the method of least squares

1810 Laplace consolidated importance of Gaussian distribution by proving the central limit theorem

1820 Gauss-Markov Theorem. Under Gaussian error assumption (actually only uncorrelated and homoscedastic needed), least square solution is the best linear unbiased estimate (BLUE), i.e., it has the smallest variance and thus MSE among all linear unbiased estimators.

So, how Gauss became famous?

- Motivated by a real problem.
- Heuristic solution: method of least squares.
- Solution readily verifiable: Ceres was re-discovered!
- Algorithmic development: linear algebra, Gaussian elimination, FFT (fast Fourier transform).
- Theoretical justification: Gaussian distribution, Gauss-Markov theorem.

**References:** Read Teets and Whitehead (1999)

## 2.2 Computer storage

*Memory unit* is the amount of data that can be stored in the storage unit. This storage capacity is expressed in terms of Bytes.

A *binary digit (bit)* is the minimum unit of binary (0 or 1) information stored in a computer system.

A group of 4 bits is called *nibble*.

A group of 8 bits is called *byte*. A byte is the smallest unit, which can represent a data item or a character.

- kB = kilobyte =  $10^3$  bytes
- MB = megabytes =  $10^6$  bytes
- GB = gigabytes =  $10^9$  bytes
- TB = terabytes =  $10^{12}$  bytes (1TB, my computer)
- PB = petabytes =  $10^{15}$  bytes

A computer system normally stores *characters* using the ASCII code. ASCII (American Code for Information Interchange) uses 7 bits, which only can store  $2^7 = 128$  characters. Extended ASCII uses 8 bits with  $2^8 = 256$  characters

For example: “STA” corresponds to 83 84 65 (Decimal number) = 01010011 01010100 01000001 (Binary number)

## 2.3 Storing real numbers

There are two major approaches to store real numbers (i.e., numbers with fractional component) in modern computing: fixed-point number system and floating-point number system.

### 2.3.1 Fixed-point number system

In a *fixed-point number system*, there is a fixed number of digits after the decimal point. A fixed-point representation of a fractional number is essentially an *integer* that is to be implicitly multiplied by a fixed scaling factor. For example, the value 1.23 can be stored in a variable as the integer value 1230 with implicit scaling factor of 1/1000 (meaning that the last 3 decimal digits are implicitly assumed to be a decimal fraction).

For negative values, the number of bits and method of representing negative numbers vary from system to system. The integer type in both R and numpy has 32 bits. The first bit indicates sign: 0 for nonnegative numbers, 1 for negative numbers.

The range of representable integers by  $M$ -bit storage unit is  $[-2^{M-1}, 2^{M-1} - 1]$ . Note that we don't need to represent 0 anymore so could have capacity for  $2^{M-1}$  negative numbers). For example, for  $M = 8$ , the range is  $[-128, 127]$ ; for  $M = 16$ , the range is  $[-65536, 65535]$ ; and for  $M = 32$ , the range is  $[-2147483648, 2147483647]$ . Hence, the smallest integer in R is  $-2^{31} + 1 = -2147483647$ . How to check this?

```
1 # Machine variable
2 > .Machine$integer.max
3 [1] 2147483647
4 > M <- 32
```

```

5 > big <- 2^{M-1}-1
6 > small <- - 2^{M-1}
7 > as.integer(big)
8 [1] 2147483647
9 > as.integer(big+1)
10 [1] NA
11 Warning message:
12 NAs introduced by coercion to integer range
13 > as.integer(small)
14 [1] NA
15 Warning message:
16 NAs introduced by coercion to integer range
17 > as.integer(small+1)
18 [1] -2147483647

```

What about in numpy? Try it by yourself.

*Two's complement* is the most common method of representing signed integers on computers, and more generally, fixed point binary values. To get the two's complement negative notation of an integer, you write out the number in binary. You then invert the digits, and add one to the result.

For example, suppose we're working with 8-bit quantities and we want to find how  $-28$  would be expressed in two's complement notation. First we write out 28 in binary form as 00011100. Then we invert the digits to make 0 become 1 and 1 become 0. We obtain 11100011. Last, we add 1 to get 11100100. That is how one would write  $-28$  in 8 bit binary. Generally speaking, an integer  $-i$  in the interval  $[-2^{M-1}, -1]$  would be represented by the same bit pattern by which the nonnegative integer  $2^M - i$  is represented.

### 2.3.2 Floating-point number system

Floating-point number system is a computer model for real numbers. The IEEE Standard 754 floating point number is composed of three parts: the sign, exponent, and mantissa.

Figure 1.1: Single and double precisions of floating-point number system

The mantissa part is first converted into a decimal by summing all  $2^{-n}$ s, where  $n$  is the position of a bit in the mantissa part that has a 1. For example, if the single precision,

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23
0	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

There is a 1 at bit number 2 and 3

The decimal part is  $2^{-2} + 2^{-3} = 1/4 + 1/8 = 0.375$ .

The formula for converting a single precision number into a decimal is given as

$$(-1)^s + (1 + \text{mantissa}) \times 2^{\text{exp} - 127}.$$

1	7	6	5	4	3	2	1	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23
1	1	0	0	0	0	0	1	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 1.2: Single precision number of  $-24.0$

For example, in Figure 1.2, we have  $s = 1$ ,  $\text{mantissa} = 2^{-1} = 0.5$ , and  $\text{exp} = 2^7 + 2^1 + 2^0 = 128 + 2 + 1 = 131$ , thus the real number is  $(-1)^1 + (1 + 0.5) \times 2^{131-127} = -1.5 \times 2^4 = -24.0$ .

To summarize:

- For the sign bit, 0 denotes a positive number, and 1 denotes a negative number. Flipping the value of this bit flips the sign of the number.
- The exponent field needs to represent both positive and negative exponents. To do this, a bias is added to the actual exponent in order to get the stored exponent. For IEEE single-precision floats, this value is 127. Thus, to express an exponent of zero, 127 is stored in the exponent field. A stored value of 200 indicates an exponent of  $200 - 127 = 73$ . For reasons discussed later, exponents of  $-127$  (all 0s) and  $+128$  (all 1s) are reserved for special numbers. Double precision has an 11-bit exponent field, with a bias of 1023.
- The mantissa, also known as the significand, represents the precision bits of the number. It is composed of an implicit leading bit (left of the radix point) and the fraction bits (to the right of the radix point).

To find out the value of the implicit leading bit, consider that any number can be expressed in scientific notation in many different ways. For example, the number 50 can be represented as any of these:

$$\begin{aligned} 0.050 \times 10^3 \\ .5000 \times 10^2 \\ 5.000 \times 10^1 \\ 50.00 \times 10^0 \\ 5000. \times 10^{-2} \end{aligned}$$

In order to maximize the quantity of representable numbers, floating-point numbers are typically stored in normalized form. This basically puts the radix point after the first non-zero digit. In normalized form, 50 is represented as  $5.000 \times 10^1$ .

Special numbers in floating-point system are stored as

**Fig. 2.4.** The Floating-Point Number Line, Nonnegative Half

**Fig. 2.5.** The Floating-Point Number Line, Nonpositive Half

**Fig. 2.6.** The Floating-Point Number Line, Nonnegative Half; Another View

**Fig. 2.7.** The Fixed-Point Number Line, Nonnegative Half

- $\pm\infty$ , sign 0 for positive and 1 for negative, exponents all 1, and mantissa part all 0
- NaN, sign either 0 or 1, exponents all 1, and mantissa anything except all 0

Take home messages:

- R and python uses double (64-bit) and 32-bit integer, they automatically convert between these two classes when needed for mathematical purposes
- Single precision:  $\pm 10^{\pm 38}$  with precision up to 7 decimal digits
- Double precision:  $\pm 10^{\pm 308}$  with precision up to 16 decimal digits
- All floating point numbers are rational because the mantissa has a fixed length. Irrational numbers stored in floating point are truncated into rational numbers, e.g.,  $\pi$
- The floating-point numbers do not occur uniformly over the real number line. (Further reading: [Here])
- Machine epsilon  $\epsilon_M$  is defined as the distance (gap) between 1 and the next largest floating point number. In single precision,  $\epsilon_M = 2^{-23}$ ; in double precision,  $\epsilon_M = 2^{-52}$ .

One can check machine epsilon in `numpy`:

$$\begin{array}{rcl}
 1 & = & 1.000000000000000000000000 \\
 1 + \text{epsilon\_m} & = & 1.000000000000000000000001 \\
 & & \quad \quad \quad \wedge \quad \quad \quad \wedge \\
 & & 2^0 \quad \quad \quad 2^{(-23)}
 \end{array}$$

Figure 1.3: Machine epsilon for single precision

```

1 import numpy as np
2
3 # Single Precision
4 eps_single = np.finfo(np.float32).eps
5 print("Single precision machine eps = {}".format(eps_single))
6
7 # Double Precision
8 eps_double = np.finfo(np.float64).eps
9 print("Double precision machine eps = {}".format(eps_double))

```

## 2.4 Computer storage and catastrophic cancellation

When dealing with big data, one should be aware of the memory storage. For example, human genome has about  $3 \times 10^9$  bases, each of which belongs to  $\{A, C, T, G\}$ . How much storage if we store 106 SNPs (single nucleotide polymorphisms) of 1000 individuals (1000 Genome Project) as characters (1GB), single (4GB), double (8GB), int32 (4GB), int16 (2GB), int8 (1GB), PLINK binary format 2bit/SNP (250MB)?

*Overflow* and *underflow* are both errors resulting from a shortage of space. *Overflow* indicates that we have done a calculation that resulted in a number larger than the largest number we can represent. For example,

```

1 > .Machine$integer.max + 1L
2 [1] NA
3 Warning message:
4 In .Machine$integer.max + 1L : NAs produced by integer overflow
5 > class(.Machine$integer.max + 1L)
6 [1] "integer"
7 > .Machine$integer.max + 1
8 [1] 2147483648
9 > class(.Machine$integer.max + 1)
10 [1] "numeric"

```

*Underflow* occurs when the true result of a floating point operation is smaller in magnitude (that is, closer to zero) than the smallest value representable as a normal floating point number. For example:

```

1 > log(exp(-745))
2 [1] -744.4401
3 > log(exp(-746))
4 [1] -Inf
5 > log(exp(-70))
6 [1] -70

```

In most situations, underflow is preferred over overflow. Overflow often causes crashes. Underflow is not a worry if the result is later added to a large number.

```

1 > 1 + exp(-746)
2 [1] 1

```

A take away message is “always try to add numbers of similar magnitude”. Try to add small numbers together before adding larger ones, and try to add numbers of like magnitude together (paring). When all numbers are of same sign and similar magnitude, add in pairs so each stage the summands are of similar magnitude.

Catastrophic cancellation occurs when an operation on two numbers increases relative error substantially more than it increases absolute error. For example, the true value for  $e^{-20} = 2.601e - 09$ . But if you evaluate using Taylor’s expansion:

$$e^{-x} = 1 - x + \frac{x^2}{2} - \frac{x^3}{3!} + \dots,$$

then you get  $6.138e - 09$ .

Example 2.  $P(A^c) \neq 1 - P(A)$

```

1 > pnorm(2.5, lower.tail = FALSE)
2 [1] 0.006209665
3 > 1 - pnorm(2.5)
4 [1] 0.006209665
5 # Same thing, right? But the latter, shorter and simpler though it may seem, suffers from
6   catastrophic cancellation.
7
8 > x <- 0:20
9 > data.frame(x, p1 = pnorm(x, lower.tail = FALSE), p2 = 1 - pnorm(x))
10      x      p1      p2
11 0 5.000000e-01 5.000000e-01
12 1 1.586553e-01 1.586553e-01
13 2 2.275013e-02 2.275013e-02
14 3 1.349898e-03 1.349898e-03
15 4 3.167124e-05 3.167124e-05
16 5 2.866516e-07 2.866516e-07
17 6 9.865876e-10 9.865877e-10
18 7 1.279813e-12 1.279865e-12
19 8 6.220961e-16 6.661338e-16
20 9 1.128588e-19 0.000000e+00
21 10 7.619853e-24 0.000000e+00
22 11 1.910660e-28 0.000000e+00
23 12 1.776482e-33 0.000000e+00
24 13 6.117164e-39 0.000000e+00
25 14 7.793537e-45 0.000000e+00
26 15 3.670966e-51 0.000000e+00
27 16 6.388754e-58 0.000000e+00
28 17 4.105996e-65 0.000000e+00
29 18 9.740949e-73 0.000000e+00
30 19 8.527224e-81 0.000000e+00
31 20 2.753624e-89 0.000000e+00

```

One can use the symmetry of the normal distribution to compute these without catastrophic cancellation and without `lower.tail = FALSE`

```

1 > x <- 7:12
2 > data.frame(x, p1 = pnorm(x, lower.tail = FALSE), p2 = pnorm(- x))
3      x      p1      p2
4 7 1.279813e-12 1.279813e-12
5 8 6.220961e-16 6.220961e-16
6 9 1.128588e-19 1.128588e-19
7 10 7.619853e-24 7.619853e-24
8 11 1.910660e-28 1.910660e-28
9 12 1.776482e-33 1.776482e-33

```

Example 3: Failure of using the short-cut formula for variance

To calculate the variance, some intro stats books call the “short-cut” formula for variance

$$\text{var}(X) = E(X^2) - E(X)^2,$$

but this serves as a perfect example to catastrophic cancellation.

Always use the two-pass algorithm

$$\bar{x}_n = \frac{1}{n} \sum_{i=1}^n x_i, \quad v_n = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x}_n)^2$$

```

1 > x <- 1:10
2 > # short cut
3 > mean(x^2) - mean(x)^2
4 [1] 8.25
5 > moo <- mean(x)
6 > mean((x - moo)^2)
7 [1] 8.25

```

So far so good. What if  $x$  is large?

```

1 > x <- x + 1e9
2 > # short cut
3 > mean(x^2) - mean(x)^2
4 [1] 0
5 > # two pass
6 > moo <- mean(x)
7 > mean((x - moo)^2)
8 [1] 8.25

```
